Testing the EMC-SRC Hypothesis with the LAD Experiment

The EMC effect, the observation that Deep Inelastic Scattering (DIS) on bound nucleons differs significantly from that on free nucleons, has puzzled nuclear physicists for more than forty years. A potential cause of this phenomenon is the formation of short-range correlations (SRCs) between nucleons within a nucleus, which may significantly alter partonic structure. This hypothesis can be tested directly using the technique of spectator-tagging, in which the coincident detection of a recoiling nucleon is used to identify when DIS occurs on a short-range correlated nucleon and the degree of its correlation. The upcoming LAD experiment in Jefferson Lab Hall C, running this winter, will measure backward-recoiling spectator protons in coincidence with DIS electrons from a deuterium target. The eponymous Large Acceptance Detector consists of three walls of plastic scintillator, which will determine proton momenta through a combination of timing and energy loss measurements. High-resolution GEM detectors will help provide crucial background suppression. I will present the current status of the preparations for LAD and showcase how its results will further our understanding of the relationship between the EMC Effect and short-range correlations in nuclei.
